"Many empirical analyses focus on estimating the structural, causal, or treatment effect of some variable on an outcome of interest. For example, we might be interested in estimating the causal effect of some government policy on an economic outcome such as employment.(...) A problem empirical researchers face when relying on a conditional-on-observables identification strategy for estimating a structural effect is knowing which controls to include." [Belloni et al., 2014, pp. 608-609].

Problem statement Context Methodology Objectives Simulation exercises Results References Problem statement

Consider the following structure [Belloni et al., 2014]:

$$\mathbf{y}_i = \alpha \mathbf{d}_i + \mathbf{x}_i' \beta_{\mathbf{g}} + \epsilon_i \tag{1}$$

$$d_{i} = x_{i}^{'}\beta_{m} + \zeta_{i} \tag{2}$$

where y_i is the response, β_g , β_m are the structural and treatments effects of variables x_i respectively, d_i is the treatment, α is the treatment effect and ϵ_i , ζ_i are stochastic errors such that

$$E\left[\epsilon_i \mid x_i, d_i\right] = E\left[\zeta_i \mid x_i\right] = 0$$

Previous	works					

Belloni et al. [2014] showed that assumptions over the distribution of $\sqrt{n}(\alpha - \hat{\alpha})$ are not always true via simulation:

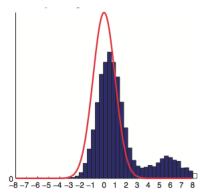

Figure: Theorical and simulated distribution, taken from Belloni et al. [2014].

Mateo Graciano-Londoño and Andrés Ramírez-Hassan Fighting Multicollinearity in Double Selection

The Lasso estimator as introduced in Tibshirani [1996] is an optimization problem which solves the following:

$$\beta^{*} = \min_{\beta \in R^{p}} \sum_{i=1}^{n} [d_{i} - x_{i}^{'}\beta_{m}]^{2} + \lambda \sum_{j=1}^{p} |\beta_{j}|$$
(3)

where λ is a penalization coefficient.

Post double LASSO estimator is a three stages procedure:

- **1** Proceed with LASSO estimator on the treatment effect.
- Proceed with LASSO estimator on the structural equation but without including the treatment.
- Proceed with a linear regression on the structural equation using the treatment and the union of variables that were selected on previews stages.

MC^3						

Markov chain Monte Carlo model composition (MC³) is a Bayesian methodology which uses a stochastic search comparing different models by its posterior model probability. As in Simmons et al. [2010], let $M = \{M_1, M_2, ..., M_m\}$ the set of models under consideration, and d the observed data as in (2).

The posterior model probability for model M_j is defined as

$$P(M_j \mid d, M) = \frac{P(d \mid M_j)\pi(M_j)}{\sum_{i=1}^{m} P(d \mid M_i)\pi(M_i)} \quad \forall j = 1, 2, ...m$$

where $P(d \mid M_j)$ is the integrated likelihood of the model M_j and $\pi(M_j)$ is the prior probability that M_j is the true model.

Problem statement Context Methodology Objectives Simulation exercises Results References MC³ with nonlocal(NL) priors

The idea of a nonlocal (to 0) prior is to effectively eliminate models with unnecessary explanatory variables, for instance consider the following nonlocal prior proposed by Johnson and Rossell [2012]:

$$\pi(\beta \mid \tau, \ \sigma^{2}, \ r, \ A_{p}) = d_{p}(2\pi)^{-p/2}(\tau\sigma^{2})^{-rp-p/2} \\ \mid A_{p} \mid^{1/2} exp\left\{-\frac{1}{2\tau\sigma^{2}}\beta'A_{p}\beta\right\} \prod_{i=1}^{p} \beta_{i}^{2r} \qquad (4)$$

where τ , r, A_p are hyper-parameters for the prior.

Problem statement	Context 000	Methodology	Objectives	Simulation exercises	Results	References
General of	objecti	ve				

Propose a double post MC3 estimators based on local and non local prior distributions, and compare its performance with the frequentist counterpart under different multicollinearity degrees.

Problem statement	Context 000	Methodology	Objectives	Simulation exercises	Results	References
Specific of	object	ives				

- Implement the post double selection and MC^3 on simulations exercises. \checkmark
- Gather real information as in Donohue III and Levitt [2001], and use both methodologies.
- Compare both methodologies and analyse how they perform based on simulation and real cases.

Model sp	oecifica	ation				

Considering (2) and (1) we define $dim(x_i) = 40$, $\alpha = 0$, β_g such that there are only 8 non zero coefficients and β_m with only 4 non zero coefficients.

We also define:

$$\begin{aligned} x_i 1 &= N_{10}(0, \Sigma) \\ x_i 2 &= N_5(0, I) \\ x_i 3 &= x_{i,j} = f_j(x_i 1, x_i 2) \\ \forall j \in \{1, 2, ..., 25\} \end{aligned}$$

where f_i is a non linear function and define.

$$x_i = (x_i 1, x_i 2, x_i 3)$$

We define three different types of experiments with different Σ to generate $x_i 1$,

- Σ so that $\sigma_{ij} \in (0.5, 0.9)$
- **2** So that $\sigma_{ij} \in (0, 0.5)$
- $\bigcirc \Sigma = I_{10}$

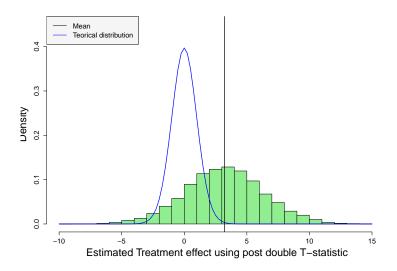

we also set the signal to noise ratio equals to 1 in both, the structural and the treatment equation.

Problem statement Context Methodology Objectives Simulation exercises Results References Defining different levels of multillinearity

	Multicollinearity level				
Measure	Type 1	Type 2	Type 3		
VIF	99.40	4.26	2.86		
Condition number	111.84	20.71	12.72		

As expected the condition number and the variance inflation factor (VIF) for the first case is clearly higher than the others due to its higher multicollinearity given by the definition of Σ in that case.

Summary	/					

	Multicollinearity level				
Procedure	Type 1	Type 2	Type 3		
Post double T	0.146	0.0699	0.0495		
Post double LASSO	0.1311	0.0732	0.0661		
Post double L-prior	0.0511	0.0488	0.0513		
Post double NL-prior	0.0551	0.0517	0.0560		
Post double ORACLE	0.0551	0.0517	0.0560		

Table: Rejection rates (at 0.05) for different set of data based on 8000 Monte Carlo simulation.

Problem statement	Context 000	Methodology	Objectives	Simulation exercises	Results	References
Summary	1					

Note that even with a high multicollinearity level Bayesian procedures has 0.05 rejection rate which is the teorical expected value.

Also it is impresive that NL-prior selection leads to the same results as the non plausible procedure post double ORACLE.
